Summary

Graves' disease, the most common form of hyperthyroidism in iodine-replete countries, is associated with the presence of immunoglobulins G (IgGs) that are responsible for thyroid growth and hyperfunction. In this article, we report the unusual case of a patient with acromegaly and a severe form of Graves' disease. Here, we address the issue concerning the role of growth hormone (GH) and insulin-like growth factor 1 (IGF1) in influencing thyroid function. Severity of Graves' disease is exacerbated by coexistent acromegaly and both activity indexes and symptoms and signs of Graves' disease improve after the surgical remission of acromegaly. We also discuss by which signaling pathways GH and IGF1 may play an integrating role in regulating the function of the immune system in Graves' disease and synergize the stimulatory activity of Graves' IgGs.

Learning points:

- Clinical observations have demonstrated an increased prevalence of euthyroid and hyperthyroid goiters in patients with acromegaly.
- The coexistence of acromegaly and Graves' disease is a very unusual event, the prevalence being <1%.
- Previous *in vitro* studies have showed that IGF1 synergizes the TSH-induced thyroid cell growth-activating pathways independent of TSH/cAMP/PKA cascade.
- We report the first case of a severe form of Graves' disease associated with acromegaly and show that surgical remission of acromegaly leads to a better control of symptoms of Graves' disease.

Background

It has been widely described that hormones can affect the development, integrity and activity of the immune system (1). In general, glucocorticoids and sex steroids depress the immune response (2, 3, 4), whereas GH, prolactin and IGF1 are considered growth and differentiation factors for lymphoid cells and increase the immune response (5, 6, 7, 8). The function of the immune system can be influenced at several levels, such as the interaction between antigen-presenting cells (APCs) and lymphocytes, mobility, migration and homing of immune cells and production of cytokines (1). Moreover, some hormones such as glucocorticoids have been shown to affect the

expression of major histocompatibility complex (MHC) molecules in APCs (9), the relationship between helper and cytotoxic T lymphocytes (10), and the interaction between idiotypes and anti-idiotypes (1).

Graves' disease, the most common form of thyrotoxicosis, has been associated with the presence of immunoglobulins G (IgGs) that are able to bind the TSH receptor (TSHR), compete with TSH and stimulate thyroid hormone synthesis and thyroid growth by increasing the cellular levels of cyclic AMP (cAMP) (11, 12, 13) as well as other second messengers, such as arachidonic acid and calcium (14, 15, 16). What is not yet known is whether

endocrine factors, in particular GH, intervene in regulating the production and synergizing the stimulatory activity of IgGs responsible for the development and maintenance of Graves' disease.

In this article, we report the unusual case of a patient suffering from Graves' disease and coexisting acromegaly and show that activity indexes of Graves' disease are substantially reduced in parallel to the surgical remission of acromegaly. We also discuss by which signaling pathways GH and IGF1 may play an integrating role in regulating the function of the immune system in Graves' disease and synergize the stimulatory activity of Graves' IgGs.

Case presentation

A 50-year-old woman was referred to us because of palpitations, tremors, excessive sweating, acral enlargement, backache and joint pains. Physical examination revealed coarsening of facial features, mild tachycardia, diffuse thyroid enlargement, accompanied by a bruit and a firm, bilateral thickening over the legs suggesting pretibial myxedema in the absence of ophthalmopathy.

Investigation

Thyroid ultrasound showed an enlarged, diffusely hypoechoic and hypervascular thyroid gland. Symptoms and signs suggested the coexistence of Graves' disease and acromegaly. Both diagnoses were confirmed by elevated free T3 (44.5 pmol/L and normal: 4.6–9.2 pmol/L), free T4 (77.6 pmol/L and normal: 9–24.5 pmol/L), GH (26.0 µg/L and normal: 0.1–2.0 µg/L), IGF1 (615 µg/L and normal: 90–260 µg/L) levels, undetectable TSH serum concentration and lack of suppression of GH to <1 µg/L following hyperglycemia during an oral glucose load. TSH binding inhibiting IgGs (TBII) concentration was measured by a commercially available radioreceptor assay. Stimulating TSHR antibodies (TSHRSAb) were also evaluated measuring cAMP generation induced by IgGs in FRTL5 thyroid cells as previously described (14). Both TBII and TSHRSAb were found extremely elevated (1758 U/L, normal: 0–10 U/L, and 1120% of the basal, normal: 100–140% of the basal, respectively). Due to TBII values above the range of calibration curve, samples were opportunely diluted in zero standard. Magnetic resonance imaging (MRI) of the pituitary revealed the presence of a 0.8 cm diameter microadenoma in the right side of the gland causing a moderate leftward shift of the pituitary stalk.

Treatment

Since the patient refused radioiodine therapy and thyroidectomy, treatment with methimazole was initiated with a 30 mg daily dose gradually tapered according to the degree of thyroid dysfunction. However, due to progressive increase in TBII/TSHRSAb concentrations, both clinical conditions and serum FT3 and FT4 levels did not allow to reduce the dose of methimazole below 20 mg per day over the next several months (Fig. 1). Due to the severe symptoms and signs of GH/IGF1 excess, treatment with octreotide long-acting release (LAR) was initiated at the monthly dose of 20 mg. After a few months the patient underwent transsphenoidal microsurgery (TSMs). The presence of a somatotroph adenoma was pathologically confirmed, and adenoma cells were positive for GH, not for other pituitary hormones, at immunocytochemistry. After surgical therapy, the acromegaly was considered 'in surgical remission' on a clinical and biochemical basis, i.e. remission of symptoms with a normal residual anterior and posterior pituitary function, normal pattern of pulsatile GH release (mean daily value: 1.5 µg/L), normal GH response to oral glucose (nadir: 0.2 µg/L) and normal IGF1 serum concentration (220 µg/L).

Outcome and follow-up

Postoperative MRI performed six months after surgery showed normal residual adenohypophysis, a normal neurohypophyseal bright spot and no residual or recurrent tumor, findings correlating with the functional preservation of the pituitary gland. Unexpectedly,

Figure 1

Serum concentrations of IGF1 and TBII and cAMP values over the course of follow-up. MMI, methimazole; TSMs, transsphenoidal microsurgery.

the patient also showed a significant improvement of all indexes of Graves' disease activity. In particular, a sharp and significant reduction in TBII/TSHRSAb concentrations was demonstrated in several controls and was accompanied by a concurrent reduction in thyroid volume (Figs 1 and 2) and a better control of the disease symptoms. At that time only it was possible to reduce the dose of methimazole to 5 mg per day.

Due to the possible coexistence of TSHR-blocking antibodies (TSHRBAb), blocking activity, defined as percent inhibition of TSH-dependent cAMP accumulation, was measured, calculated with the following formula: $\{1 - [\text{cAMP accumulation in the presence of TSH (1 IU/mL) and patient IgG/cAMP accumulation in the presence of TSH and normal IgG}]\} \times 100$, and found negative in all samples (data not shown).

Statistical analysis

Data were analyzed using GraphPad Prism 6 software (GraphPad Software Inc., La Jolla, CA, USA). All data are presented as the means $\pm$ S.E.M. and were first checked for normality using the D'Agostino-Pearson normality test. A two-sample unpaired Student's *t*-test was applied to analyze the differences in thyroid volumes, TBII, cyclic AMP and IGF1 before and after TSMS. A $*P < 0.05$ was considered significant.

Figure 2
(A) IGF1, (B) TBII concentrations, (C) cAMP production and (D) thyroid volumes before and after transsphenoidal microsurgery (TSMS). Results are shown as means $\pm$ S.E.M. of pre- ($n=44$) and post-TSMS ($n=40$) determinations, **** $P < 0.0001$.

Discussion

The regulation of thyroid function and growth has been well characterized and appears to be related to stimuli acting through the G protein-coupled receptor (GPCR) TSHR, like TSH and Graves' IgGs, and the tyrosine kinase (TK) IGF1 receptor (IGF1R), like IGF1 (17).

Three types of TSHR antibodies have been described in patients with autoimmune thyroid disease: stimulating (TSHRSAb), blocking (TSHRBAb) and cleavage antibodies. The biological activity varies among the different classes of these autoantibodies. The proportion of these differing antibodies contributes to the different phenotypes of Graves' disease (18). These autoantibodies activate distinct G proteins and signaling pathways. Thus, TSHRSAb recognize epitopes in extracellular domain of TSHR, activate $G_{\alpha s}$ /AC/PKA/CREB-Erk, $G_{\alpha q}$ /PLC/PI₃K/Akt and $G_{\alpha q}$ /PKC/Erk/Elk pathways and are responsible for thyroid cell proliferation and function and survival (Fig. 3).

TSHR-blocking and cleavage antibodies bind to separate TSHR epitopes and induce different signaling cascades with a recognized weak agonist activity (19).

The relationship between thyroid function and GH/IGF1 axis has been the subject of a number of reports. However, previous studies on hyper- or hypothyroid acromegalic patients have been almost exclusively focused on the relation between thyroid status and GH secretion. Thus, the release of GH has been shown to be blunted in hypothyroidism (20), whereas a normal (20, 21, 22), decreased (23, 24) or increased (25) GH response to provocative stimuli have been reported in hyperthyroidism. Conversely, elevated serum levels of GH are known to be a cause of goiter development (26, 27, 28, 29). The stimulation of proliferation and differentiation of thyroid cells occurs via the activation of IGF1R that are expressed on the thyroid cell membrane (30, 31, 32, 33). The appearance of goiter and the coexistence of frank hyperthyroidism have been reported in 18–50% and 5% of acromegalic patients, respectively (28, 34, 35), most of these patients being suffering from non-autoimmune forms of hyperthyroidism (36). Moreover, thyroid volume and nodularity correlate with disease duration (37).

In this article, we show that GH and IGF1 play a role in influencing the production of autoantibodies directed against the TSHR, exacerbating TSHR-induced Graves' thyrotoxicosis.

By what mechanism GH and IGF1 may potentiate the action of TSHRSAb and influence the severity of Graves' disease?

Figure 3

Diagrammatic representation of the TSH and IGF1 signaling pathways, which are demonstrated to be involved in the regulation of function, growth and survival of follicular cell. Note that $PI_3K/PDK1/Akt/mTOR$ cascades are common to TSHR and IGF1R signaling pathways.

GH is involved in immunoregulation acting upon a cell by binding its receptor at the cell membrane. The GH receptor (GHR), which is copiously expressed on B lymphocytes, less in T lymphocytes (7, 38), belongs to the cytokine receptor superfamily. GHR is not a tyrosine kinase, but associates with the nonreceptor ubiquitous Janus activating kinase (JAK) 2 that transduces GH-mediated signals inducing phosphorylation of transcription factor substrates, including members of the signal transducer and activator of transcription (STAT) family, mainly STAT5b that is regarded as the major effector of GH action (39, 40). Besides STAT5b, JAK2 also phosphorylates members of the (i) Shc/Grb2-SOS/Ras/Raf/MAPK/Erk and (ii) IRS/PI₃K/PDK1/Akt pathways (Fig. 4) that cross-talk with STAT5b to influence gene expression and cell proliferation (39).

Evidence from previous studies has demonstrated that GH enhances proliferation of T cells (41) and human B cell immunoglobulin production and proliferation *in vitro* (42). Moreover, the GH effect is not mediated by IGF1 (43). Thus, GH might *per se* stimulate the TSHRSAb production by B lymphocytes.

IGF1 affects the development and function of both T and B lymphocytes and thyrocytes by binding the tyrosine kinase IGF1R. A number of studies have clarified the influence exerted by the activation of the IGF1/IGF1R signaling pathway on many aspects of immune function (44). Briefly, activation of IGF1R results in the recruitment and phosphorylation of multiple adaptor proteins and activation of multiple downstream pathways including (i) IRS1/IRS2 activating PI₃K/PDK1/Akt pathway; (ii) Shc linked to the Ras/MAPK/fos-jun pathway by recruitment of Grb2/SOS complex and (iii) the JAK/STAT pathway

(Fig. 3). Thus, IGF1 promotes maturation and proliferation, stimulates glucose metabolism and inflammatory cytokine production in T lymphocytes and maintains T cell survival inhibiting apoptosis gene expression (44, 45). Moreover, it plays a key role in B cell differentiation (46).

IGF1 as well as other members of IGF family cooperate with TSH in regulating thyroid function and growth. The relationship between IGF1R and TSHR has been demonstrated in pioneering reports by Tramontano and coworkers showing a synergistic and dose-dependent effect of IGF1, TSH and Graves' immunoglobulins on DNA synthesis and thyroid cell proliferation (47, 48). Moreover, other groups have showed that GPCR/cAMP/PKA signaling activates PI₃K/Akt pathway, confirming that Ras, Akt and PI₃K, downstream effectors of the IGF1R

Figure 4

The growth hormone signaling pathways in B cells.

signaling, are also involved in TSH/cAMP-induced thyroid cell proliferation (49, 50, 51).

Together, all the above-mentioned data show that thyroid cell function and proliferation is regulated by the activation of the G protein-coupled TSHR as well as the tyrosine kinase IGF1R and may represent the molecular basis that substantiates our assumption that elevated concentrations of GH and IGF1 play a role in determining the severity of hyperthyroidism in this patient. GH and IGF1 may act by multiple mechanisms: (i) by stimulating T cell proliferation and inflammatory cytokine production by T cells infiltrating the thyroid; (ii) by stimulating B cell immunoglobulin production and proliferation and (iii) by promoting post receptor pathways directly in thyroid cells, how it more frequently occurs in non-autoimmune thyroid growth. Nevertheless, some questions may arise. First, the alternate circumstance that TSH simultaneously secreted by the pituitary adenoma could have occurred. However, the negativity for TSH at immunocytochemistry, the undetectable levels of TSH and the positivity of TBII and TSHRSAb exclude the possibility that this patient was suffering from a non-autoimmune form of hyperthyroidism due to the production of TSH by the pituitary adenoma. Second, theoretically, the concurrent presence of TSHRAB might have played a role in reducing the severity of Graves' disease neutralizing the activity of TSHRSAb. Actually, this possibility has been excluded based on the negativity of TSHRAB assay throughout the entire follow-up.

Similar to patients with other autoimmune diseases, Graves' patients may enter remission spontaneously or after a course of medical therapy. Thionamide drugs (methimazole or its pro-drug carbimazole and propylthiouracil), which are commonly used in the treatment of Graves' disease, have been suggested to have important direct immunosuppressive effects such as inhibition of thyroid autoantibody production (52, 53), increase of activated and total circulating CD8⁺ cells (54) and reduced numbers of intrathyroidal and thymic lymphocytes (55). However, over the years, clinical studies of Graves' disease patients have questioned the immunosuppressive hypothesis on the basis of the following findings: (i) the fall in TSHR antibodies is seen independently of the type of drug (methimazole or perchlorate) (56); (ii) the fall in TSHR antibodies is similar during therapy with a thionamide drug and after surgical therapy (57); (iii) the fall in TSHR antibodies as well as the risk of relapse of Graves' disease is seen independently of neither the dose of thionamide nor the levothyroxine replacement (58). Thus, it could be argued

that a simultaneous and coincidental improvement of acromegaly and Graves' disease might be occurred in this patient. Indeed, regardless of the debate about the possible immunosuppressive effect of thionamide drug, our data clearly show that the decrease of autoantibody titers and the amelioration of clinical condition of our patient seem clearly to be related to surgical remission of acromegaly (Fig. 1).

In conclusion, the present case illustrates the uncommon occurrence of Graves' disease and acromegaly. Biochemical data clearly showed that hyperthyroidism in this patient was due to a severe form of Graves' disease. The activity of Graves' disease, as evaluated by the ability of patient's IgG to block TSH binding and induce the production of cyclic AMP, goes parallel to the activity of acromegaly, based on abnormal concentration of IGF1 (as shown in Fig. 1), confirming the assumption that GH/IGF1 axis may play an important role in maintaining the activity and exacerbating the clinical course of Graves' disease. Thus, this patient might be considered an *in vivo* model for studying the action of GH/IGF1 axis on immune system in Graves' disease patients.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding

This research did not receive any specific grant from any funding agency in the public, commercial or not-for-profit sector.

Patient consent

The authors have obtained informed consent from the patient for publication, which is enclosed along with manuscript.

Author contribution statement

A D C, physician of the patient, performed both physical and instrumental examinations and wrote the paper. A D C performed the statistical analysis and performed data interpretation. F P participated in manuscript drafting and discussed the results. All authors read and approved the final manuscript.
