Summary

Enteroviruses, including coxsackieviruses and Echovirus, are well known pathogens responsible for the development of thyroiditis. We describe the case of a 49-year-old woman with no personal or family history of thyroid disease who presented to the emergency room with a two-week history of daily fevers up to 39°C, a sore throat, occasional palpitations and diaphoresis, decreased appetite and an unintentional 10 kg weight loss over the same time course. Physical examination revealed mild tachycardia, an intention tremor and a normal-sized, nontender thyroid gland without palpable nodules. The remainder of the physical examination was unremarkable and without stigmata of Graves' disease. Her initial blood tests revealed overt thyrotoxicosis, elevated liver enzymes, an elevated C-reactive protein, a negative monospot and a positive CMV IgM antibody. Thyroid sonography revealed areas of hypoechogenicity and relatively low vascularity. Fine-needle biopsy showed a lymphocytic infiltrate. The patient was treated symptomatically with propranolol. On follow-up, the patient became euthyroid, and her liver enzymes normalised. Previous cases of CMV-induced thyroiditis occurred in immunosuppressed patients. This is the first reported case of a CMV-mononucleosis-induced thyroiditis in an immunocompetent adult patient and serves as a reminder that viral illnesses are a common cause of thyroiditis with abnormal liver enzymes.

Learning points:

- The differential diagnosis of thyrotoxicosis with abnormal liver enzymes includes severe hyperthyroidism and thyroid storm caused by Graves' disease as well as the thyrotoxic phase of a thyroiditis, usually caused by a virus such as coxsackievirus or, in this case, cytomegalovirus.
- Cytomegalovirus appears to be a recently recognized causal agent for thyroiditis, both in immunosuppressed and immunocompetent patients.
- Careful follow-up of thyroid function tests in patients with thyroiditis allows clinicians to determine if patients' thyroid hormone secretion normalizes or if they remain hypothyroid.

Background

Subacute thyroiditis is characterized by an initial phase of thyrotoxicosis with neck pain, a tender diffuse goiter and elevated thyroxine (T₄) and/or triiodothyronine (T₃). The classic pattern of changes in thyroid function in patients with thyroiditis is thyrotoxicosis, followed by hypothyroidism, and then recovery within 8–12 weeks.

During the thyrotoxic phase, thyroid hormone synthesis and thyroid radioiodine uptake are low, in contrast to Graves' disease in which they are elevated. Therefore, the thyrotoxicosis lasts only until the stores of T₄ and T₃ are depleted, which corresponds usually to a two- to six-week period. Hypothyroidism is also

usually transient, but can occasionally be permanent. Lymphocytic thyroiditis is painless and often referred to as silent thyroiditis.

A viral infection or post-viral inflammatory process is thought to cause thyroiditis, because many patients have a history of an upper respiratory tract infection preceding the onset, and clusters of cases have occurred in association with epidemics of coxsackievirus or other enteroviruses (1).

To our knowledge, this case is the first report of a cytomegalovirus-mononucleosis-induced thyroiditis in an immunocompetent adult patient, as other cases were reported in an immunosuppressed adult and in an infant.

Case presentation

A 49-year-old woman with no personal or family history of thyroid disease, primary or secondary immune deficiency and who takes no medication including any immunosuppressant, presented to the emergency room of our hospital with a two-week history of daily fevers up to 39°C, a sore throat, occasional palpitations and diaphoresis, decreased appetite and an unintentional 10kg weight loss over the same time course. She denied ocular symptoms, compressive symptoms, anterior neck pain or other symptoms of thyrotoxicosis.

Physical examination revealed mild tachycardia (HR 105bpm, regular) with normal vital signs otherwise, an intention tremor and a normal-sized, nontender thyroid gland without palpable nodules. The patient had no thyroid stare or lid lag. The remainder of the physical examination was unremarkable and without stigmata of Graves' disease, such as ophthalmopathy or dermopathy.

Her initial blood test revealed overt thyrotoxicosis (TSH: 0.06 U/L (normal: 0.40–4.59 U/L)), free T4: 48.9 pmol/L (normal: 9.0–26.0 pmol/L), elevated transaminase levels (ALT: 261 U/L (normal: 5.0–40.0 U/L)), AST: 203 U/L (normal: 15.0–55.0 U/L), an elevated

C-reactive protein at 23.3 mg/L (normal: 0–10.0 mg/L) and a negative monospot but a positive CMV IgM antibody (c.f. Table 1). Of note, thyroglobulin, thyroglobulin antibodies and anti-TPO antibodies were not ordered. The infectious disease service diagnosed acute active cytomegalovirus mononucleosis and treated her conservatively.

The next morning, she was seen in Endocrinology Clinic and given the clinical suspicion of thyroiditis; she was treated symptomatically.

Investigation

Seven days after her initial presentation, a 24-h radioactive iodine uptake disclosed a 24% uptake of I-131 at 24 h, the normal range being 8–28% at our institution (Fig. 1). The uptake was uniform in bilateral thyroid lobes with a photopenic region in the right superior lobe. Although we recognize it is not typical of the thyrotoxic phase of a painless thyroiditis, given the clinical context of acute CMV mononucleosis concurring with thyrotoxicosis, we interpreted the normal range I-131 uptake on thyroid scan as a resolving thyroiditis as it was probably performed in the recovery or transition phase.

TSH receptor antibody titer was weakly positive. We believe that the mildly positive TSH receptor antibodies are suggestive of a sensitization process during the course of the thyroiditis, rather than Graves' disease. This is supported by the fact that the antibody titer as well as sonographic features normalized over time during follow-up.

Three weeks after her initial ER visit, a thyroid sonography revealed areas of hypoechogenicity and relatively low vascularity diffusely in the thyroid gland. Fine-needle aspiration biopsy of the area in the right superior thyroid lobe corresponding to a photopenic area on the uptake scan was performed the same day. No nodule or cyst was seen on the thyroid ultrasound, suggesting that the photopenic region may have been due to inflammation. Of note, the ultrasound was not

Table 1 Biochemical investigation of the patient.

Test	Day 1	Day 7	Day 10	Day 37	Day 427	Normal range
TSH	0.06	0.31	0.22	1.19	2.71	0.40–4.59 U/L
Free T4	48.9	23.3	22.8	16.2	15.8	9.0–26.0 pmol/L
Free T3		6.2		5.1	4.9	2.8–7.1 pmol/L
TRAb		3.0			0.8	0–1.2 U/L
ALT	261	134	95	21	21	5.0–40.0 U/L
AST	203		55			15.0–55.0 U/L
CRP	23.3				2.5	0–10.0 mg/L
CMV IgM	Positive					Negative
Monospot	Negative					Negative

repeated during follow-up. Pathology report described a small amount of colloid and few strips of small follicular cells. The pathologist interpreted the FNA biopsy result as nondiagnostic and the CMV immunostain was negative, which may have been secondary to the paucity of cells in the sample.

Overall, given the clinical picture, we hypothesized that this immunocompetent 49-year-old woman had developed thyroiditis as a consequence of her CMV mononucleosis. Other diagnostic possibilities include incipient Graves' disease or a viral-induced autoimmune thyroiditis. Given this differential diagnosis, we ensured the patient is followed with regular thyroid function tests to monitor for development of hyperthyroidism.

Treatment

For her adrenergic symptoms, the patient was started on propranolol 40mg po bid on her first visit to the Endocrinology clinic. However, the patient discontinued propranolol on her own as she felt it did not improve her symptoms. Due to the absence of thyroid pain (spontaneous or upon palpation), she was given neither NSAIDs nor prednisone. Given that thyroiditis was our most likely diagnosis, we did not start the patient on any anti-thyroid drug such as methimazole or propylthiouracil.

Outcome and follow-up

During the follow-up period of sixteen months, the patient had no recurrence of symptoms of thyrotoxicosis.

Similarly, she always remained biochemically euthyroid, her TSH receptor antibodies and her liver enzymes normalised during follow-up.

Discussion

In summary, our patient is an immunocompetent 49-year-old woman who developed thyroiditis following an episode of cytomegalovirus-induced mononucleosis, explaining her presenting symptoms and clinical picture.

A MEDLINE search from 1950 to the present using the terms 'cytomegalovirus', 'thyroiditis', 'hyperthyroidism', 'thyrotoxicosis', 'CMV' and 'mononucleosis' found two similar case reports.

André and coworkers (2) reported a 47-year-old man with psoriatic arthritis treated with infliximab who presented with daily fevers. Apart from fever, his result was unremarkable and his thyroid was nontender. His thyroid function tests showed overt thyrotoxicosis, a high CRP, negative TSH receptor antibodies, but a high CMV PCR. His thyroid uptake scan showed low uptake and ultrasound showed increased gland volume with hypoechoic signal. The patient's symptoms, thyroid function tests and CMV PCR normalized with holding infliximab.

Al Maawali and coworkers (3) described an 18-month old infant girl who developed a painful subacute thyroiditis secondary to CMV mononucleosis. She had high fevers and a mildly painful right neck mass. Her thyroid function tests were normal, but she had a high WBC count, high CRP and ESR and CMV IgM count. Her thyroid ultrasound revealed a diffuse hypoechogenic enlargement of her right lobe without abscess formation. Her thyroglobulin titer was elevated. FNA biopsy was negative for Gram stain and culture. TSH receptor antibodies and thyroid uptake scan were not performed in this infant. She was initially started on amoxicillin-clavulanate, but it was later stopped, and she was managed symptomatically.

Our patient had similar symptoms, physical examination findings (including a painless thyroid) and laboratory findings as in case by André and coworkers. However, as opposed to that case, our patient was immunocompetent, her thyroid uptake was within normal range at seven days and her TSH receptor antibodies were transiently mildly positive.

When compared to case by Al Maawali and coworkers, our patient did not have a painful thyroid, but her laboratory and ultrasonographic features were similar. As TSH receptor antibodies were not drawn and a

thyroid uptake scan was not performed for this infant girl, comparison between both cases is limited.

In a review by Desailoud and coworkers (4), one article revealed positive cultures for mumps virus in biopsies of two patients out of a cohort of 11 patients with subacute thyroiditis and mumps during an epidemic (5). With regards to serological evidence of acute viral infection in patients with subacute thyroiditis, a study of 58 patients with subacute thyroiditis, who had no clinical evidence of viral disease, viral antibody titers of 32 patients demonstrated increases at least fourfold. These included antibodies to mumps virus, but also coxsackie, adenovirus and influenzae. Coxsackie viral antibodies were the most commonly found, and the changes in their titers most closely approximated the course of the disease (6).

In conclusion, there seems to be an association between cytomegalovirus as a causal agent for painless thyroiditis as well as painful thyroiditis. Laboratory and imaging findings may differ between cases. The age and integrity of the patient's immune system may explain these clinical differences. Although direct thyroid invasion or serological evidence of acute infection have been reported in patients with thyroiditis and other viruses, more extensive research is needed to elucidate the link between cytomegalovirus and thyroiditis to help guide clinicians in managing such cases.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding

The research did not receive any specific grant from any funding agency in the public, commercial or not-for-profit sector.

Patient consent

The patient provided written consent for the publication of this article.

Author contribution statement

Dr M Tamilia is the Endocrinologist who was on service and initially saw the patient in clinic the day following her ER presentation. He also performed an ultrasound and a fine-needle aspiration biopsy on the patient's thyroid. Dr V Larouche is the Endocrinology resident who was on service, saw the patient with Dr M Tamilia and followed up her case in clinic in the weeks following her initial presentation.
